Mass segregation trends in SDSS galaxy groups

2.1 Introduction

It has been well established that galaxy properties depend strongly on local environment (e.g. Oemler, 1974; Hogg et al., 2004; Blanton et al., 2005a; Tal et al., 2014). Galaxies in dense environments such as clusters tend to have lower star formation rates (SFRs), while isolated field galaxies are generally actively forming stars (e.g. Balogh et al., 2000; Ball et al., 2008; Wetzel et al., 2012). It is also well known that galaxy properties, such as SFR, depend strongly on galaxy mass (e.g. Poggianti et al., 2008). It is critical to study the distribution of galaxy masses within haloes of different masses in order to ascertain whether the variations in galaxy properties with environment are due to physical mechanisms acting in dense environments, or simply due to the fact that high-density environments contain more high-mass galaxies. Intermediate-density environments, galaxy groups, represent not only the most common environment in the local Universe (Geller & Huchra, 1983; Eke

et al., 2005), but also represent the environment where many physical processes are efficient. Galaxy interactions such as mergers and harassment are favoured in this environment because of the low relative velocities between galaxies (Zabludoff & Mulchaey, 1998; Brough et al., 2006).

The study of mass segregation in groups can be used to elucidate information on physical processes such as dynamical friction, galaxy mergers, and tidal stripping. Mass segregation in bound structures has generally been predicted as a result of dynamical friction (Chandrasekhar, 1943). Dynamical friction acts as a drag force on orbiting bodies and massive galaxies within groups and clusters are expected to migrate to smaller radii as time progresses. If dynamical friction is a dominant factor, then clear mass segregation should be observed in evolved groups and clusters.

Galaxy groups are not static systems, but are constantly being replenished by infalling galaxies from the field. Infalling galaxies are preferentially found at large radii (Wetzel et al., 2013) and the difference in stellar mass distributions between evolved group members and infalling galaxies could affect the strength of mass segregation.

If significant mass segregation is not found, then this implies that either: the time-scale associated with dynamical friction is greater than the age of the group/cluster, or that there are other physical processes, such as merging, tidal stripping, or pre-processing, which are playing a more important role than dynamical friction.

Recent work has shown conflicting results with regards to the presence of mass segregation in groups and clusters. Ziparo et al. (2013) find no evidence

for strong mass segregation in X-ray selected groups out to $z = 1.6$, for a sample of galaxies with $M_{\text{star}} > 10^{10.3}M_{\odot}$. von der Linden et al. (2010) examine Sloan Digital Sky Survey (SDSS) galaxy clusters and find no evidence for mass segregation in four different redshift bins at $z < 0.1$. von der Linden et al. make redshift-dependent stellar mass cuts ranging from $10^{9.6}$ to $10^{10.5}M_{\odot}$. Vulcani et al. (2013) use mass-limited samples at $0.3 \leq z \leq 0.8$ from the IMACS Cluster Building Survey and the ESO Distant Cluster Survey, with stellar mass cuts at $M_{\text{star}} > 10^{10.5}M_{\odot}$ and $M_{\text{star}} > 10^{10.2}M_{\odot}$, respectively, to study galaxy stellar mass functions in different environments. Vulcani et al. find no statistical differences between mass functions of galaxies located at different cluster-centric distances.

Conversely, Balogh et al. (2014) find evidence for mass segregation in Group Environment Evolution Collaboration 2 (GEEC2) groups at $0.8 < z < 1$, using as stellar-mass-limited sample with $M_{\text{star}} > 10^{10.3}M_{\odot}$. Using a volume limited sample of zCOSMOS groups, Presotto et al. (2012) find evidence for mass segregation in their whole sample at both $0.2 \leq z \leq 0.45$ and $0.45 \leq z \leq 0.8$. Presotto et al. also break their sample into rich and poor groups at $0.2 \leq z \leq 0.45$, and find evidence for mass segregation within rich groups but find no evidence for mass segregation within poor groups. Using a V_{max} -weighted sample with a stellar mass cut at $10^{9.0}M_{\odot}$, van den Bosch et al. (2008) find evidence for mass segregation in SDSS groups.

It is clear that there is no consensus regarding the strength of mass segregation in groups and clusters or its halo mass dependence.

In this Letter, we present evidence of the presense of a small, but significant, amount of mass segregation in SDSS galaxy groups. We show that the detection of mass segregation is dependent on stellar mass completeness, with completeness cuts at relatively high stellar masses potentially masking underlying mass segregation trends. We also show that the strength of mass segregation scales inversely with halo mass, with cluster-sized haloes showing little to no observable mass segregation. In Section 2.2, we briefly describe our data set, in Section 2.3 we present our results from this work, in Section ... we provide a discussion of our results, and in Section ... we give a summary of the results and make concluding statements.

In this Letter, we assume a flat Λ cold dark matter cosmology with $\Omega_M = 0.3$, $\Omega_\Lambda = 0.7$, and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

2.2 Data

The results presented in this Letter utilize the group catalogue of Yang et al. (2007). This catalogue is constructed by applying the halo-based group finder of Yang et al. (2005, 2007) to the New York University Value-Added Galaxy Catalogue (NYU-VAGC; Blanton et al. 2005b), which is based on the SDSS Data Release 7 (DR7; Abazajian et al. 2009). Stellar masses are obtained from the NYU-VAGC and are computed using the methodology of Blanton & Roweis (2007), assuming a Chabrier (2003) initial mass function. Halo masses are determined using the ranking of the characteristic stellar mass, $M_{\star, \text{grp}}$, and assuming a relationship between M_{halo} and $M_{\star, \text{grp}}$ (Yang et al., 2007). $M_{\star, \text{grp}}$ is defined by Yang et al. as

$$M_{\star,\text{grp}} = \frac{1}{g(L_{19.5}, L_{\text{lim}})} \sum_i \frac{M_{\text{star},i}}{C_i}, \quad (2.1)$$

where $M_{\text{star},i}$ is the stellar mass of the i th member galaxy, C_i is the completeness of the survey at the position of that galaxy, and $g(L_{19.5}, L_{\text{lim}})$ is a correction factor which accounts for galaxies missed due to the magnitude limit of the survey.

Halo-centric distance for each galaxy is not given explicitly in the Yang catalogue; however, we calculate it using the redshift of the group and the angular separation of the galaxy and halo centre on the sky. We measure group-centric radius from the luminosity-weighted centre of each group, and normalize our group-centric radii by R_{200} . We use the definition for R_{200} as given in Carlberg et al. (1997)

$$R_{200} = \frac{\sqrt{3}\sigma}{10H(z)}, \quad (2.2)$$

where the Hubble parameter, $H(z)$, is defined as

$$H(z) = H_0 \sqrt{\Omega_M(1+z)^3 + \Omega_\Lambda}, \quad (2.3)$$

and we calculate the velocity dispersion, σ , as

$$\sigma = 397.9 \text{ km s}^{-1} \left(\frac{M_{\text{halo}}}{10^{14} h^{-1} \text{M}_\odot} \right)^{0.3214}, \quad (2.4)$$

where the above is a fitting function given in Yang et al. (2007).

For our analysis we select group galaxies with redshift, $z < 0.1$, that are within two virial radii of the group centre, and groups with a minimum of three galaxy members – although our results are not sensitive to these specific cuts. For our sample over 95 per cent of group galaxies reside within two virial radii of the group centre. We also subtract the most massive galaxy (MMG) from each group, to ensure that any underlying radial mass trend is not contaminated by the MMG.

This sample is not volume limited, therefore, the sample will suffer from the Malmquist bias. This leads to a bias towards objects of higher luminosity and stellar mass, with increasing redshift. To account for this bias we weight our sample by $1/V_{\text{max}}$, where V_{max} is the comoving volume of the Universe out to a comoving radius at which the galaxy would have met the selection criteria for the sample. For our V_{max} weights we apply the values presented in the catalogue of Simard et al. (2011) to our sample.

In order to investigate the effect of stellar mass limits on the detection of mass segregation, we use samples corresponding to various stellar mass cuts. We perform our analysis on an unweighted sample with two mass cuts corresponding to $M_{\text{star}} > 10^{10.5}M_{\odot}$ (4152 galaxies in 1970 groups) and $M_{\text{star}} > 10^{10.0}M_{\odot}$ (26 774 galaxies in 4534 groups); and a V_{max} -weighted sample with mass cuts at $M_{\text{star}} > 10^{9.0}M_{\odot}$ (56 957 galaxies in 7217 groups) and $M_{\text{star}} > 10^{8.5}M_{\odot}$ (59 791 galaxies in 7289 groups). The unweighted sample is stellar mass complete down to $M_{\text{star}} > 10^{10.0}M_{\odot}$. Therefore, for both the weighted and unweighted sample, we have two different stellar mass cuts, giving us four separate samples in total.

2.3 Results

2.3.1 Mass segregation in SDSS groups

Figure 2.1 All panels show mean mass as a function of normalized distance for various halo mass bins, with error bars corresponding to 1σ statistical errors. The solid lines correspond to weighted least-squares fits for each halo mass bin. Top left: unweighted sample, for galaxies with $\log(M_{\text{star}}/M_\odot) > 10.5$. Top right: unweighted sample, for galaxies with $\log(M_{\text{star}}/M_\odot) > 10.0$. Bottom left: V_{max} -weighted sample, for galaxies with $\log(M_{\text{star}}/M_\odot) > 9.0$. Bottom right: V_{max} -weighted sample, for galaxies with $\log(M_{\text{star}}/M_\odot) > 8.5$. Note that different mass scales are used in each panel. There are more halo mass bins in the bottom row due to the increased number of low-mass galaxies as a result of V_{max} weighting.

In Fig. 2.1 we plot mean stellar mass as a function of radial distance from the group centre for various halo mass bins. Fig 2.1(a) corresponds to our

high-mass cut, unweighted sample; Fig 2.1(b) corresponds to our low-mass cut, unweighted sample; Fig 2.1(c) corresponds to our high-mass cut, weighted sample; and Fig 2.1(d) corresponds to our low-mass cut, weighted sample.

For all halo mass bins, and regardless of the mass cut, the unweighted sample shows statistically significant mass segregation with a weighted linear least-squares fit. The V_{max} -weighted sample shows statistically significant mass segregation for the five lower halo mass bins, whereas the highest halo mass bin has a best-fitting slope consistent with zero – this trend hold for both mass cuts. For both the weighted and unweighted samples there is a clear trend of the slope with halo mass – more massive haloes show weaker mass segregation. This result will be discussed in Section ...

We find that our highest halo mass sample ($M_{\text{halo}} > 10^{14.5} M_{\odot}$) has a large number of low-mass galaxies when compared to the high-halo-mass samples, which leads to a smaller mean stellar mass in the V_{max} -weighted results shown in Figs 2.1(c) and (d). While this introduces a shift in normalization, it does not affect the mass segregation trend and therefore does not change the key result that mass segregation depends on halo mass.

2.3.2 Massive galaxy fraction

An alternative way to investigate galaxy populations within the group sample is to study the fraction of ‘massive’ galaxies at various group-centric radii. In Fig..., we plot the fraction of massive galaxies as a function of radial distance for two different definitions of what constitutes a massive galaxy. We calculate the massive fraction for each radial bin as

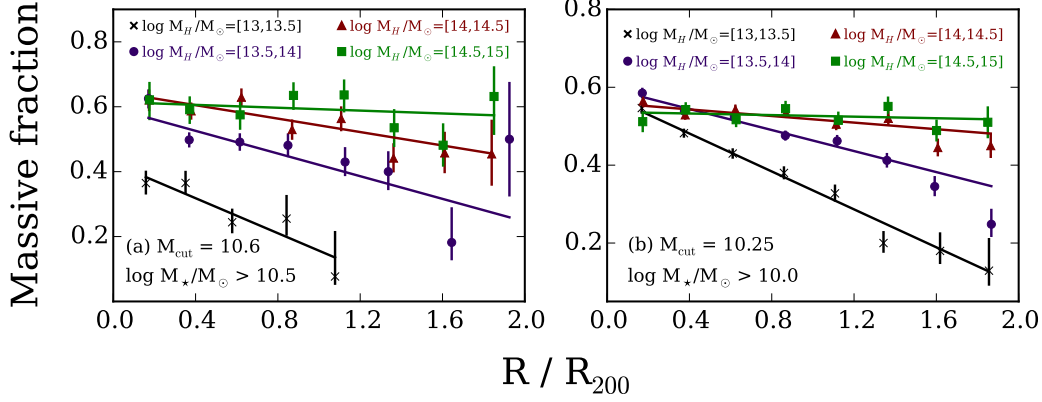

Figure 2.2 Fraction of massive galaxies with respect to normalized radial distance. Error bars are given by a 1σ binomial confidence interval, calculated using the beta distribution as outlined in Cameron (2011). The solid lines correspond to weighted least-squares fits for each halo mass bin. Left-hand panel: the fraction of galaxies with $\log(M_{\text{star}}/M_\odot) > 10.25$ as a function of radial distance, for the unweighted sample with $M_{\text{star}} > 10^{10}M_\odot$. Right-hand panel: the fraction of galaxies with $\log(M_{\text{star}}/M_\odot) > 10.5$ as a function of radial distance, for the unweighted sample with $M_{\text{star}} > 10^{10}M_\odot$.

$$f_m(M_{\text{cut}}) = \frac{\# \text{ galaxies with } M_{\text{star}} > M_{\text{cut}}}{\# \text{ galaxies with } M_{\text{star}} > 10^{10}M_\odot}, \quad (2.5)$$

where M_{cut} is a stellar mass cut-off above which we define a massive galaxy. We initially apply a high-mass galaxy cut, M_{cut} , at $10^{10.25}M_\odot$, corresponding to the median stellar mass of the unweighted sample (with the low-mass cut at $10^{10}M_\odot$). Comparing Figs 2.1(b) and 2.2(a) we see essentially identical trends. We observe the same trends of mass segregation whether we look at the average galaxy mass at a given radius, or consider the fraction of massive galaxies.

To confirm that this trend is robust regardless of the mass cut-off used to define a massive galaxy, we make the same plot but now use $M_{\text{cut}} = 10^{10.5}M_\odot$. Comparing Figs 2.2(a) and (b) we see that while the overall fractions of massive

galaxies decrease with increasing the stellar mass cut, the trend essentially stays the same. There is clear evidence for mass segregation and the strength of mass segregation depends on halo mass.

2.4 Discussion

2.4.1 Effect of including low-mass galaxies

The results in Fig. 2.1 show that mass segregation generally increases when lower mass galaxies are included. To quantify this effect we can compare the best-fitting slopes corresponding to the high-mass and the low-mass cut samples.
